

### Abstract

A possibility of geophysical measurements using the large scale laser interferometrical gravitational wave antenna is discussed. An interferometer with suspended mirrors can be used as a gradiometer measuring variations of an angle between gravity force vectors acting on the spatially separated suspensions. We analyze restrictions imposed by the atmospheric noises on feasibility of such measurements. Two models of the atmosphere are invoked: a quiet atmosphere with a hydrostatic coupling of pressure and density and a dynamic model of moving region of the density anomaly (cyclone). Both models lead to similar conclusions up to numerical factors. Besides the hydrostatic approximation, we use a model of turbulent atmosphere with the pressure fluctuation spectrum  $\sim f^{-7/3}$  to explore the Newtonian noise in a higher frequency domain (up to 10 Hz) predicting the gravitational noise background for modern gravitational wave detectors. Our estimates show that this could pose a serious problem for realization of such projects. Finally, angular fluctuations of spatially separated pendula are investigated via computer simulation for some realistic atmospheric data giving the level estimate  $\sim 10^{-11}$  rad·Hz $^{-1/2}$  at frequency  $\sim 10^{-4}$  Hz. This looks promising for the possibility of the measurement of weak gravity effects such as Earth inner core oscillations.

## Introduction

A possibility of geophysical measurements with large scale laser interferometrical gravitational wave antenna [1, 2] was discussed in [3, 4]. It was supposed that at very low frequencies  $10^{-3} - 10^{-5}$  Hz the interferometer with suspended mirrors can be considered as an angular gravity gradiometer measuring variations of the mutual angle between gravity force vectors or plumb lines of spatially separated suspensions. Geophysical information could be read out as error signal of the feedback circuits which preserves the operational angle position of the mirrors.

As an example of geophysical phenomenon for the measurement a very weak effect of the Earth inner core oscillations (one of “hot points” of modern geophysics [5]) was considered in [4].

A number of principal instrumental problems were analyzed in [6, 7] (such as a necessity of suspension for the laser injection bench, the problem of tilt and shift differentiation for spherical mirrors, and others); the main part of instrumental noises at low frequencies was estimated in [7] where a positive conclusion was drawn in favor of a feasibility of geophysical measurements. However, environmental geophysical fluctuations produce a predominant noise background which can be a problem while realizing this program. It is clear that, for any gravitational device, the fundamental and unavoidable source of noises is the gravitational attraction of stochastically moving surrounding masses, the so-called “Newtonian gravity noise.” Such noise produced by acoustic waves, propagating under the interferometer base ground, was calculated in [8] at high frequency  $f \geq 10$  Hz typical for gravitational detectors.

In this paper, we estimate, at least at the order of magnitude, the Newtonian fluctuations of the mutual angle between two separated plumb lines (suspended

mirrors) produced by atmospheric perturbations; preliminary results were presented in [9].

Stochastic density variations and transportation of large air masses produces a contribution into the gravity force on the Earth surface. Almost all processes of such kind are connected with the corresponding pressure changes. Thus they can be controlled by means of pressure monitoring. In the gravimetry theory, it is well known that the influence of atmospheric pressure on the gravity consists of direct attraction of the atmospheric mass and crust deformation due to atmospheric loading [10].

The both effects have the same order of magnitude but the loading effect, as a rule, is at least two-five times less than the direct attraction. For this reason, below we consider only the direct attraction effect as one of main contributions to the atmospheric Newtonian noises.

As a control reference point in our analysis, we bear in mind an acceptable level of the noise spectrum density which allows one to register the inner core oscillations with amplitudes of the order of 1 m — the expected signal can achieve  $10^{-13} - 10^{-14}$  rad for the interferometer base equal to 3 km [2, 5]. Suppose that the period and quality factor of the inner core of the fundamental mode are  $\tau_0 = 3.3 h$  and  $Q = 10^2 - 10^3$ , respectively [11]. Then one can take the measurement time  $\tau_m = 10^6$  sec which results in the following angular noise spectrum limit  $\delta\alpha_f = 10^{-11} \text{ rad}\cdot\text{Hz}^{-1/2}$ .

## 1 Plane atmosphere

A very rough and simple Earth atmospheric model is a half-space filled by air stratum of the homogeneous density  $\rho$  of the altitude  $h$ . A change in the gravity acceleration  $\Delta g$  caused by perturbation of the atmospheric density can be estimated as follows [12]

$$\Delta g_z = \frac{2\pi G}{g} \Delta p, \quad (1)$$

where  $\Delta p$  is the atmospheric pressure variation,  $g$  is the gravity acceleration,  $G$  is Newtonian gravity constant and  $z$ -axis is directed upward. The factor of admittance between the gravity and pressure  $k_p = 2\pi G/g = 0,427 \mu\text{Gal/hPa}$  is widely used in geophysics and is in a fair correspondence with experimental data. One can easily get (1) starting with the surface field of the stratum  $g_z = 2\pi G\rho h$  and using a hydrostatic coupling between the pressure and density  $p = \rho gh$  if one supposes very slow variations.

Although this formula has an integral sense, one can likely use it in a spectral form by substituting the corresponding spectral densities of the gravity and pressure variables, having in mind the fact that the changes of pressure are mostly quasistatic processes, i.e. the factor of admittance does not depend on frequency.

After this, the relative angular deflection of two plumb lines located at the ends of the interferometer's base can be evaluated phenomenologically, in view

of the following expression:

$$\langle \delta\alpha \rangle \simeq \xi \frac{\Delta g_x}{g} \frac{L}{L_p} = \xi \frac{k_p}{g} \frac{L}{L_p} |p(f)| \sqrt{\Delta f}, \quad (2)$$

where  $L$  is the arm's length,  $L_p$  is the scale of the pressure anomaly domain (cyclone size, etc.),  $p(f)$  is the spectral density of the pressure amplitude in the bandwidth  $\Delta f$  and  $\xi \ll 1$  is a coupling factor between vertical  $g_z$  and horizontal  $g_x$  components of gravity variations.

To evaluate the  $\xi$  factor, we suppose that pressure changes along the  $x$ -direction so slowly, that (1) remains to be valid and it leads to the condition  $h \ll L_p$ . Then using the potential character of the gravity field, i.e.,  $\text{rot } \mathbf{g} = 0$ , one can take  $\partial g_x / \partial z = \partial g_z / \partial x$ , or  $\Delta g_x / h \simeq \Delta g_z / L_p$ . This results in the estimation

$$\xi = \frac{\Delta g_x}{\Delta g_z} \simeq \frac{h}{L_p} \ll 1$$

which might be used while calculating in view of formula (2).

The pressure time variation background was investigated by many meteorological observatories in different places. In spite that it is a local characteristic, there are typical common features in the spectrum density such as the diurnal ( $1.17 \cdot 10^{-5}$  Hz) and semidiurnal ( $2.33 \cdot 10^{-5}$  Hz) peaks, a general upward slope at very low frequencies, etc. For numerical estimations at the order of magnitude, we used data collected by the Mizusawa Astrogeodynamic Observatory (Japan) from 1986 to 1987.

Available data [13] can be approximately separated into three following spectral domains with the dominant spectral amplitudes, namely,

$$\begin{aligned} (a) \quad & (2 \cdot 10^{-5} - 2.5 \cdot 10^{-5}), \quad |p(f)| = 9 \cdot 10^2 \text{ mBar/Hz}^{1/2} \\ (b) \quad & (1,5 \cdot 10^{-5} - 8 \cdot 10^{-6}), \quad |p(f)| = 1,9 \cdot 10^3 \text{ mBar/Hz}^{1/2} \\ (c) \quad & (3 \cdot 10^{-6} - 5 \cdot 10^{-7}), \quad |p(f)| = 9,5 \cdot 10^3 \text{ mBar/Hz}^{1/2}. \end{aligned}$$

This demonstrates that a transition from time-scale of several hours (a) to time-scale of several days (b) is accompanied by the increase in the pressure fluctuations, in average, of one order of magnitude. One can see that the domain of several hours (a) overlaps with the tidal semidiurnal spectrum peak, which can be removed while data processing, so it is reasonable to take for estimation a decreased (but still dominant) extrapolation value  $1 \cdot 10^2 \text{ mBar/Hz}^{1/2}$  for the times  $3 \div 4$  hours (inner core polar mode). Then taking as typical average pressure anomaly the (cyclone) size  $L_p = 500 \text{ km}$  and the effective atmosphere altitude  $h = 10 \text{ km}$ , one obtains the following result for the standard angle deviation between arm's mirrors

$$\langle \delta\alpha \rangle \simeq \frac{k_p}{g} \frac{hL}{L_p^2} |p(f)| \sqrt{\Delta f} \simeq 5 \cdot 10^{-12} \sqrt{\Delta f} \text{ rad}. \quad (3)$$

This estimation does not exceed the critical noise density mentioned in Introduction although it shows difficulties in the detection of the inner core motion

because the angular noise is at the border of the expected gravity effect. However, it is supposed that a correction for the gravity atmospheric noise could be carried out if one would precisely control pressure variations in the location of front and end mirrors.

## 2 Cyclone dynamic effect

An obvious lack of the previous consideration is an uncertainty of the  $\xi$  factor which cannot be rigorously found within the framework of the homogeneous static model of the atmosphere. To avoid this uncertainty, it would be useful to consider a more complex dynamic model where some spatially limited domain inside the atmospheric half space, called below as “cyclone” (characterized by perturbed parameters of density and pressure) moves along the interferometer base. Then a direct calculation of its Newtonian attraction permits one to get a more reliable estimation of mutual angular deflections of the interferometer arm’s mirrors.

It is convenient to take the cyclone form as an oblate ellipsoid of rotation because its gravitational field can be expressed in terms of elementary functions [14]. After this, the problem is formulated as follows. The cyclone (ellipsoid of rotation) with its plane of symmetry on the Earth surface moves along the  $x$  axis where the interferometer arm is located (figure 1). Only upper half of the ellipsoid has a physical sense representing the cyclone, so that an effective gravitational field along the  $x$ - axis must decrease twice. A vertical size of the cyclone (a minor ellipsoid semiaxis  $c$ ) is approximately equal to the atmosphere altitude in  $z$  direction ( $c \leq h$ ), however, it is much less than a horizontal size of the cyclone, a major semiaxis  $a$  ( $a \gg c \sim h$ ). Let us take a Cartesian coordinate system in the cyclone center in such a way that the current value  $x$  is just the distance between the cyclone and interferometer centers. The positions of the front and end suspended mirrors are  $(x-L/2)$  and  $(x+L/2)$ , with  $L$  representing the interferometer arm length. The cyclone pass through the interferometer base corresponds to the  $x$  variation in the limits  $(+\infty; -\infty)$ .

For a homogeneous ellipsoid, its gravity field (acceleration) along the  $x$  axis grows linearly with the distance from the center inside the figure ( $x \leq a$ ), while outside ( $x \geq a$ ) it can be described by the following expression

$$g_x = -2\pi G\rho \frac{a^2 c}{A^2} \left( \eta^{-1} \sqrt{\eta^2 - 1} - \eta \arcsin \eta^{-1} \right), \quad (4)$$

where  $A^2 = a^2 - c^2$ ,  $\eta = x/A$  and  $\rho$  is an excess (or deficit) of air density over the average density of unperturbed atmosphere.

In principle, formula (4), in combination with the corresponding formula inside the figure, gives a possibility to determine dynamic perturbations of mirror’s plumb lines when the cyclone is penetrating through the base. However, it is much more convenient to operate with the field of a thin ellipsoid shell to avoid a necessity of the transition between two different field expressions.

To get formula for the shell field, it is enough to accept  $c = ka$  and then to differentiate  $g_x$  (4) as a function of the variable  $a$ . This procedure results in the following formula:

$$dg_x = 4\pi G \rho k \frac{a^2 da}{x \sqrt{x^2 - a^2(1 - k^2)}}. \quad (5)$$

Expression (5) presents the gravitational field outside the shell ( $x \geq a$ ), meanwhile, the internal field is equal to zero, the factor  $da$  is the shell's thickness in the cross point with the  $x$  axis. Then the field of inhomogeneous cloud at the points of  $x$  axis can be calculated in terms of the integral

$$g_x = 4\pi G k \int_0^x \frac{a^2 \rho(a) da}{x \sqrt{x^2 - a^2(1 - k^2)}}, \quad (6)$$

where the function  $\rho(a)$  defines the cyclone density distribution (the maximum horizontal size of the cyclone, hereinafter, noted as  $a_0$ ).

The mutual angular deflection of mirror's suspensions located at the ends of the interferometer base is given by the simple combination of the function  $g_x(x)$  in two particular points of the  $x$  axis:

$$\delta\alpha = \frac{g_x(x + L/2) - g_x(x - L/2)}{2g}. \quad (7)$$

Factor 2 in the denominator reflects the effect of the upper part of the ellipsoid cloud only, i.e. the domain where  $z \geq 0$ . For transition to the time domain, one has to substitute  $x = vt$ , where  $v$  is the cyclone velocity.

To illustrate a general type of the angular deflection dynamics, formulas (6) and (7) were calculated numerically for several artificially selected laws of the density variation over the cyclone. Four types of the density distributions were considered, namely, "step," "circle," "harmonic" and "Gaussian" (see figure 2, curves 1a–1d) with the same normalization of mean value and variance:

$$\int \rho(x) k x^2 dx = (\pi/2) \bar{\rho} a_0^2 c, \quad \int \rho(x) k x^4 dx = (\pi/2) \bar{\rho} a_0^4 c.$$

Corresponding plots are presented in figure 2. Density distributions used for calculations are presented by curves 1a–1d and curves 2a–2d show the dynamics of relative variations of the mirror's plumb lines. For numerical calculations, it was used  $v=1$  m/sec and the other parameters were  $a_0=300$  km,  $c=10$  km,  $\bar{\rho}=0.02$  kg/m<sup>3</sup> and  $L=3$  km.

Figure 2 demonstrates a strong dependence of the mutual angular deflection on the density distribution inside the cyclone. Common features are peaks of deflection at the cyclone base borders and a suppression of perturbation inside the cyclone. The amplitudes of peaks depend on the density structure of the cyclone cloud. The homogeneous cloud produces the biggest jump of deflection (case a). The Gaussian distribution minimizes the jump effect (case d). However, the best compensation of perturbations inside the cyclone takes

place just for the homogeneous model (here the mutual deflection is more close to zero then in the other cases).

For the homogeneous model (case a), the integral in (6) can be calculated analytically. Results of such calculation within the first order accuracy of the parameter  $(c/a_0) \ll 1$  read

$$\begin{aligned} g_x(x) &\simeq -\pi^2 \rho G \frac{c}{a_0} x & \text{for } |x| \leq a_0; \\ (\partial g / \partial x) &\simeq \pi^2 \rho G \frac{c}{a_0} & \text{for } |x| \leq a_0; \\ \Delta g &= g_x(x + L/2) - g_x(x - L/2) \simeq g_x|_{x=a_0} \frac{L}{a_0}. \end{aligned}$$

For the mutual angular deflection, one has

$$\delta\alpha \simeq \frac{\Delta g}{2g} \simeq \frac{\pi^2 \rho G c}{2g} \frac{L}{a_0} = \frac{\pi}{4} k_p \frac{c}{v_s^2} \frac{L}{a_0} \Delta p. \quad (8)$$

The adiabatic coupling between the pressure and density variations  $(\rho/\rho_0) = (\Delta p/p_0)$  was used to obtain relationship (8), where  $v_s^2 \simeq p_0/\rho_0$  is the sound velocity in the normal atmosphere and  $\Delta p$  is the pressure jump outside the cyclone. By comparing (8) with phenomenological formula (3), one can see that the formulas are similar. For  $c \simeq h \simeq 10$  km,  $(h/v_s^2) \simeq 1/g$  ( $v_s = 330$  m/sec) one obtains  $\xi \sim 1$  for the rough homogeneous model, but it decreases up to 0.01 for more smooth cyclone shapes.

From figure 2 it is clear that a more favorable cyclone structure can be presented by a cloud with Gaussian fronts and long plane central zone. Then jump perturbations corresponding to the cyclone front passing through the interferometer base are suppressed as well as perturbations in the central part of the cloud. In general, large sharp perturbations (corresponding to relatively rare events) can be obviously controlled by barometric measurements. At quiet atmospheric conditions, the usual daily variation is of the order of  $(1 \div 10)$  mBr, that keeps the effect of Newtonian atmospheric attraction, in view of (8), at the level of  $10^{-11} \div 10^{-12}$  rad.

Nevertheless, it is by two-three order of magnitude larger than the inner core oscillation effect ( $\sim 10^{-13} \div 10^{-14}$  rad). However, (8) gives the integral value of the atmospheric gravity effect and one has to evaluate its spectrum noise density in the domain of interest at  $f \simeq (10^{-4} \div 10^{-3})$  Hz.

Let us consider Poissonian flux of cyclones with average number  $\bar{n}$  per time unit. Excluding the cases of recovering, one can take  $\bar{n} \leq v/2a$ . The well-known formula for the power spectrum of the Poissonian flux defined by the spectrum of individual events reads

$$S_\alpha(f) = \bar{n} |\delta\alpha(f)|^2, \quad (9)$$

where  $\delta\alpha(f)$  is the Fourier component of the angle deflection. It is clear *a priori* that the spectrum maximum takes place near  $f \sim v/a = 10^{-6}$  Hz independently

of the cyclone density distribution. The spectrum behavior at high frequencies strongly depends on the cyclone density structure. The main role is played by the peak amplitude at the border  $x = vt = a$ . For the thin ellipsoid shell, the peak amplitude is  $4\pi G\rho da$  and it gives the elementary gravity variation spectrum

$$dg_x(f) = \frac{4\rho Gv}{f} \cos \frac{2\pi a f}{v}.$$

It has to be integrated over the cyclone cloud in order to get the total gravity spectrum

$$g_x(f) = \int_0^{a_0} dg_x(f) = \frac{4Gv}{f} \rho \left( \frac{2\pi f}{v} \right), \quad (10)$$

i.e. it is essentially determined by the cloud density spectrum  $\rho$ . To obtain the mutual angular spectrum of plumb lines, one has to multiply (10) by the transfer function of the differential link (7). Numerical calculations for the four selected cyclone clouds are presented in figure 2 by curves 3a–3d.

Let us consider the homogeneous cyclone (case a) in more detail. The integrand in (10) is calculated analytically and the final result for the angular deflection power spectrum reads

$$\delta\alpha(f) = \frac{4\rho Gv^2\sqrt{n}}{\pi f^2} \sin\left(\frac{2\pi a}{v}f\right) \sin\left(\frac{\pi L}{v}f\right) \sqrt{\Delta f}. \quad (11)$$

At  $f > v/L \simeq 10^{-4}$  Hz, the spectrum oscillates and falls down as  $1/f^4$  and at low frequencies  $S_\alpha \sim 1/f^2$ . At frequency  $f \sim 10^{-4}$  Hz (interesting for us), the angular spectrum density equals to  $2 \cdot 10^{-9}$  rad·Hz $^{-1/2}$ , that is two order of magnitude larger than the acceptable level. However, it follows from the very sharp density jump in the homogenous cyclone model. For more smooth cyclone structure, the angular spectrum at high frequencies goes down much faster:

$$\begin{aligned} S_\alpha &\sim 1/f^3 \text{ (3b);} \\ S_\alpha &\sim 1/f^4 \text{ (3c);} \\ S_\alpha &\sim \exp -f^2 \text{ (3d).} \end{aligned}$$

From figure 2 one can see, that at frequency  $10^{-4}$  Hz the amplitude of angular noise is already less than the critical level  $10^{-11}$  rad·Hz $^{-1/2}$  (3c) and then it becomes negligible (3d).

Analysis presented in sections 1 and 2 elucidates particular characteristics of the free mass interferometer such as a gravity gradiometer one. Being a gravity device, it is affected by all environmental movements of masses. But its transfer function suppresses the influence of large scale homogeneous gravity sources by the factor of the ratio of the base length to the source scale. The most effective sources would be those which generate the gravity field with a space scale equal to the interferometer base (or less). Such sources might have a typical variation time of the order of tens seconds for  $v \geq 10$  m/sec, so it would be high frequency sources with respect to the main geophysical processes with times equal to hours and longer. It is clear also that, by suppressing the Newtonian environmental noise, the gravity gradiometer suppresses equally low frequency (quasistatic)

signals arising from the objects (including the inner core oscillations). However, it cannot be a serious objection if instrumental (intrinsic) noises of the device are enough small to permit measurements of such very weak effects. It seems that modern advanced technology of gravitational interferometers under construction could meet these requirements.

### 3 Turbulent flux efect

The previous consideration was carried out at the condition of the hydrostatic atmosphere or, at least, slow laminar air currents. However, it is known that in upper troposphere strata the Reynolds number can be very high  $Re > 10^6$  and appearance of turbulent currents is a typical event. The rigorous calculation of the turbulent atmosphere gravity effect is complicated due to an uncertainty in constructing the models adequate to our problem, many unknown parameters and general complexity of the theory of turbulent atmosphere. For the estimation of the order of magnitude of the gravity noise produced by the air turbulence, we hope that a simple phenomenological consideration based on the Kolmogorov–Obukhov (K-O) law [15] can be useful. This law fixes relative variation of velocities of vortex zones with different scales in the regime of developed turbulence.

Let  $a$  be some maximum size of the turbulence zone with an average amplitude of the velocity variations  $V$ . Then according to the K-O law, a velocity standard  $v_\lambda$  at the small scale  $\lambda \leq a$  obeys to the formula

$$v_\lambda \simeq V \left( \frac{\lambda}{a} \right)^{1/3}. \quad (12)$$

For each  $\lambda$ , one can define the frequency of the velocity fluctuation as  $f = V/\lambda$ . Then (12) can be rewritten as

$$v_\lambda = V^{4/3} (f a)^{-1/3}. \quad (13)$$

Following [16] the pressure standard  $\Delta p$  is introduced in (10) through the hydrodynamic law at the scale  $\lambda$ :

$$\Delta p_\lambda \simeq \frac{\rho v_\lambda^2}{2},$$

while the variance  $\langle (\Delta p)^2 \rangle$  is composed by contributions of all turbulent scales  $\lambda$ , or corresponding frequencies  $f(\lambda)$  from a minimal scale, say,  $\lambda_0$  up to the current value  $\lambda$ , i.e.

$$\langle (\Delta p)^2 \rangle = \int_{f(\lambda)}^{f(\lambda_0)} S_p(f) df \simeq \text{const} - \int_0^{f(\lambda)} S_p(f) df. \quad (14)$$

Here  $S_p(f)$  is the spectral power density of the pressure variations and the approximation  $\lambda_0 \simeq 0$ ,  $f(\lambda_0) \simeq \infty$  was used.

Differentiating (14) over frequency and taking into account (13), one obtains the well-known spectrum of developed turbulence

$$S_p(f) \simeq \left(\frac{\rho}{3}\right)^2 V^{16/3} a^{-4/3} f^{-7/3}. \quad (15)$$

The frequency domain where the spectrum (15) is valid reads

$$\frac{V}{a} = f_2 \leq f \leq f_3 = \frac{V}{a} \text{Re}^{3/4}.$$

At frequencies  $f < f_2$  (the domain of slow hydrodynamic changes), the pressure variations conventionally obey to the  $\Delta P \sim f^{-1}$  law (velocity fluctuations  $v_\lambda$  are considered as independent), so the pressure spectrum in this domain reads

$$S_p(f) \simeq \frac{d(\Delta P)^2}{df} = S_0 f^{-3}. \quad (16)$$

Here the constant  $S_0$  can be determined by the condition of uninterrupted spectra in the point  $f_2$  for both approaches under consideration. It is obvious also that the lowest conceivable frequency associated with the limited turbulence zone is  $f_1 = V/R_e$ , where  $R_e$  is the Earth radius. Below this point, the spectrum of pressure variations remains to be uncertain at least within the framework of the approach used.

This simple model of the turbulent atmosphere pressure spectrum does not take into account all complex processes which could take place. So, experimental observations of thunder storms in the frequency domain ( $10^{-2} \div 10^{-4}$ ) Hz gives the spectrum indices distributed, in average, between 2 and 4.25 and centered in the point 3.5 [17], i.e. larger than the K-O index 7/3. On the contrary, at frequencies below  $10^{-4}$ , experimental data better agree with index 5/3 [18], i.e. low frequency fluctuations grow slowly than it is predicted by the flicker type noise with the spectrum index 3, and so on.

Nevertheless, this model at the quiet atmosphere conditions corresponds to the real experimental data by the order of magnitude. In particular, it was successfully used for calculating the atmospheric load deformations measured by strain meters at the Obninsk Seismic Station (see [16]). In figure 3 (adopted from [16]), one can compare the model spectrum calculated for the turbulent zone with kinetic parameters  $a = L = 18$  km,  $V = \Delta U = 3$  m/sec and average density  $\rho_0 = 0.55$  kg/m<sup>3</sup> (corresponding altitude  $h = 8$  km) with the experimental pressure spectrum measured at the Obninsk Seismic Station. One can see a satisfactory coincidence, at least, by the order of magnitude.

Now we discuss the gravity noise associated with a turbulent atmospheric process. For this, let us consider the plane atmosphere with effective altitude  $h$  filled by the turbulent flux as it was considered in section 2. The estimation of gravity variations on the Earth surface is taken as follows

$$\Delta g \simeq 2\pi G h \Delta \rho.$$

The average density changes  $\Delta\rho$  over the total scale of turbulent zone can be replaced by the average pressure standard deviation using the adiabatic law, i.e.

$$\Delta g \simeq 2\pi G \frac{\rho_0 h}{p} \Delta p. \quad (17)$$

The mutual plumb lines deflection has to be a function of the pressure gradient, i.e.

$$\delta\alpha \simeq \frac{1}{2g} \frac{\partial \Delta g}{\partial x} L = \frac{1}{2g} 2\pi G \frac{\rho_0 h}{p^2} \left( \frac{\partial p}{\partial x} L \right) \Delta p. \quad (18)$$

(In this approximation, we suppose that the standard pressure deviations do not depend on  $x$ ). To evaluate the pressure gradient along the interferometer base, one can employ again the K-O law or use direct experimental data provided by some spatial barometric grid. Below we consider both methods.

One can express the pressure gradient along a turbulence cell ( $\lambda \sim L$ ) in terms of the spatial derivative of the local relation  $p = \rho_0(v_\lambda^2/2)$

$$\frac{\partial p}{\partial x} = \rho_0 v_\lambda \frac{\partial v_\lambda}{\partial x} = L \rho_0 \frac{v_\lambda}{L} \frac{\partial v_\lambda}{\partial x}. \quad (19)$$

If  $v_\lambda$  is not known, one can take it from the K-O law,  $v_\lambda = V(L/a)^{1/3}$ , and then, in view of the linear dependence of the velocity on  $x$ , i.e.  $(v_\lambda/L) \simeq (\partial v_\lambda / \partial x)$ , one obtains

$$\frac{\partial p}{\partial x} \simeq L \rho_0 \left( \frac{V}{L} \right)^2 \left( \frac{L}{a} \right)^{2/3} \sim 10^{-2} \text{ hPa/km}, \quad (20)$$

where the parameters in figure 3 used for numerical estimation are  $a=18$  km,  $V=3$  m/sec and the interferometer base  $L=3$  km.

This very approximate estimation is supported by experimental data provided by the barometric space pattern covered several hundred kilometers around the Brussels [10]. Measured value of the pressure gradient along the East–West direction was in average 0.037 hPa/km (and 0.085 hPa/km in the Nord–South direction). This (by the order of magnitude) is in a satisfactory agreement with theoretical calculation. Below, we use the intermediate value  $5 \cdot 10^{-2}$  hPa/km for estimations.

To transform formula (18) for the relative angular variations of arm mirrors, one can substitute  $(\rho_0/p_0) = v_s^2$  and use the K-O spectrum (15) for estimating the standard deviation  $\Delta p$ . It results in the formula for angle deflection

$$\langle \delta\alpha(f) \rangle \simeq \frac{\pi G h}{p g v_s^2} \frac{\partial p}{\partial x} L \langle S_p(f) \rangle^{1/2} \sqrt{\Delta f}. \quad (21)$$

For numerical estimations, let us take the following parameters:  $v_s=330$  m/sec, the average pressure magnitude  $p = 10^3$  hPa, the pressure jump at the arm ends

$$\Delta p_L = \frac{\partial p}{\partial x} L = 0.05 \text{ hPa/km} \cdot 3 \text{ km} = 0.15 \text{ hPa},$$

and the pressure spectrum density

$$S_p(f = 0.001\text{Hz}) \simeq 10^3 \text{ Pa}^2/\text{Hz}.$$

As a result, one obtains  $\langle \alpha(f) \rangle \simeq 2 \cdot 10^{-14} \text{ rad}\cdot\text{Hz}^{-1/2}$ . The noise is proved to be small enough to be neglected in measurements of the Earth core gravity oscillations.

It is worthy to estimate a residual Newtonian angular noise in the frequency domain typical for gravitational wave detectors, i.e. above 10 Hz. Following the K-O law the numerical result must be multiplied by the factor  $(10 \text{ Hz}/0.001 \text{ Hz})^{-7/5} = 2.5 \cdot 10^{-6}$ , that yields  $\langle \alpha(10 \text{ Hz}) \rangle \simeq 5 \cdot 10^{-20} \text{ rad}\cdot\text{Hz}^{-1/2}$  (the frequency 10 Hz just corresponds to the upper boundary of validity of the K-O approach if  $\text{Re} \geq 10^6$ ,  $V=3 \text{ m/sec}$ ,  $a=20 \text{ km}$ ).

For VIRGO superattenuator, a length of suspension is of the order of 10 m, it provides the interferometer optical arm variations on the level of  $5 \cdot 10^{-17} \text{ cm}/\text{Hz}^{1/2}$ . This means that there exists a deformation noise at  $1.7 \cdot 10^{-22} \text{ Hz}^{-1/2}$ , which might create some problems for advanced VIRGO project.

## 4 Simulation of plumb lines deflection

To test a likelihood of our estimations, we carried out a simple computer simulation of the angular dynamics of two separated plumb lines (pendula) in a variable pressure field. Real experimental data were kindly provided by Japanese Weather Association. These data were collected by the Meteorological National Geographical Institute at the area close to Tsukubo Scientific Center. The area 20x20 km was covered by 10 meteostations with an average intermediate distance 10 km. The pressure data were registered at each station with a sample time 1 min. An accuracy of measurement was 0.01 %. The recorded signal contained obvious diurnal oscillations of the pressure; the average value of these oscillations was 0.1 % of atmospheric pressure ( $\sim 100 \text{ Pa}$ ), meanwhile, the differential pressure amplitude for neighbour stations had only 10 % accuracy.

For modeling the angular free-mass interferometer response, we used the simple hydrostatic approach calculating the mutual angle between plumb lines of suspensions according to the formula

$$\Delta\alpha \sim 2\pi \frac{GhL}{gv_s^2} \frac{p_i - p_k}{|r_{ik}|}, \quad (22)$$

where  $p_i$  is the pressure at the  $i$ -station,  $r_{ik}$  is the distance between neighbour stations (a linear interpolation  $p(\kappa x) = \kappa p(x)$ ,  $\kappa \leq 1$  was used). In figure 4 (a,b), the spectrum of mutual angular fluctuations for pendula separated by the distance  $L$  is shown. It demonstrates the flicker noise at zero frequencies, diurnal peak and a moderate noise level  $\leq 10^{-11} \text{ rad}\cdot\text{Hz}^{-1/2}$  at times over few hours. In fact, real noise can be less because the noise level in figure 4 is determined just by the unsufficient accuracy of the pressure measurements.

## 5 Conclusions

Our estimations as well as computer simulation of the pendula behaviour in real variable pressure field show that, under normal atmospheric conditions, the mutual angle between two suspensions spatially separated by 3–4 km fluctuates with the standard spectral deviation of the order of  $10^{-11} \text{ rad}\cdot\text{Hz}^{-1/2}$  in the frequency domain  $10^{-3} \div 10^{-4} \text{ Hz}$ , although some rare events (cyclones, storms, etc.) can produce one–two order larger perturbations. Such events, however, can be forecasted in advance, registered and removed from standard data records, or simply the measurements must be eliminated in such times. Thus it is quite possible to achieve the desirable accuracy  $\sim 10^{-13} \div 10^{-14} \text{ rad}$  for the measurement time of  $10^4 \div 10^6 \text{ sec}$  for detecting the inner core motion.

Our rough approximations of gravity noises for the turbulent atmosphere have shown that the high frequency tail of Newtonian atmospheric fluctuations can provide some difficulty for gravitational wave detection at very low frequencies  $f \leq 10 \text{ Hz}$ . This point, however, requires a more detailed investigation with more adequate models of turbulent currents in the high atmosphere.

## Acknowledgments

Authors appreciate kind assistance of the Japan Meteorological Agency, Mr. Yuzo Arisawa and Dr. Akihiko Itagaki for providing observational data collected by the Tsukubo Meteorological Station.

Authors express their gratitude to Prof. Isao Naito and Prof. Masa-Katsu Fujimoto from NAO, Japan for their interest to this work and discussions.

We got many useful information and critical remarks from our colleagues: Prof. G. S. Golitzin, Prof. S. N. Kulichkov from the Atmosphere Physics Institute of the Russian Academy of Sciences and Prof. A. B. Manukin and Prof. Yu. A. Gusev from the Earth Physics Institute of the Russian Academy of Sciences.

This work was partially supported by RS Grant (UK) No RCPX331.
